Keywords: Amino Acids, Derivatives, Atherosclerosis

Our special interest in the study of the role of amino acids in the pathogenesis, prevention and treatment of atherosclerosis and its accompanying cardiovascular pathology in circulatory failure is due to several reasons. So, atherosclerosis is characterized not only by disturbances in the metabolic flows of carbohydrate (inhibition of gluconeogenesis and activation of glycolysis), lipid (activation of lipolysis, ketosis), but also protein (protein- and hypoalbuminemia), hyperglobulinemia and negative nitrogen balance [1-18].

There is comparatively little data in the available literature on changes in the spectrum (pool, fund) of free plasma amino acids against the background of atherosclerosis. Only a few works are devoted to a comparative assessment and interpretation of changes in the pool of free amino acids at different stages of atherosclerosis and in the dynamics of its treatment [19]. The question of the information content of the established changes in the levels of individual amino acids in atherosclerosis and their significance in comparison with other clinical and biochemical criteria remains practically unclear. The unresolved problem of the choice of individual amino acids in the amino acids used for the directed correction of metabolic imbalance in atherosclerosis.

The importance of amino acids in the regulation of the functions of pathological conditions (vasoaterogenesis, arterial thrombosis) of the cardiovascular system has been convincingly established in a number of studies. Repeatedly described is a decrease in blood lipid levels under the action of glycine and its derivatives, the positive effect of cysteine and aspartate in patients with hyperlipidemia, the lipid-lowering effect of arginine in plasma [21].

High concentrations of amino acids and their derivatives in platelets have been demonstrated, upon activation of which the agonist binds to a specific receptor, forming a complex through which an energy signal that activates phosphatase and mobilizes ionized calcium from the dense tubular system to the cytoplasm is transmitted [22,23].

A study of the amino acid sequences of glycoprotein receptor polypeptides that specifically bind hem coagulation substrates showed the possibility of inhibiting platelet aggregation, adhesion and blood clot formation using synthetic and natural (snake venom) polypeptides containing arginine, glycine, asparagine, valine, proline, phenylalanine and cysteine [24].

The role of free amino acids in the processes of tissue ischemia tolerance and post ischemic recovery deserves special attention [25]. The protective effect of branched chain amino acids-BCAA (valine, leucine, and isoleucine) in the myocardium is manifested in the maintenance of contractility, macroerg levels (ATP, creatinine phosphate), normalization of aortic and coronary blood flow, cardiac output and cardiac output. The BCAA activates the production of catabolites of the adenine system during post ischemic reperfusion [65], activates the utilization of introduced amino acids to high-energy substrates of Krebs cycle, and helps to restore the functional capabilities of smooth muscle structures [26].

Recently, the role of amino acid derivatives, biogenic amines, in the development of the pathology of the cardiovascular system, the progression of thrombosis and damage to the vascular wall with the simultaneous activation of platelet function has been proven [27]. An increase in the content of
adrenaline and norepinephrine in the blood, together with an increase in the content of other vasoconstrictor biogenic amines in the blood of patients with atherosclerosis, has been established at an evidence-based level. The predominance of $\alpha$-adrenergic receptors in arterial blood creates the conditions for the occurrence of vasoconstriction [28]. Thus, in patients with atherosclerosis, the activity of mono oxidase in the blood utilizing biogenic amines (serotonin, tyramine, and tryptamine) is significantly reduced, which creates the conditions for the manifestation of vascular effects of vasoconstrictor amines [29].

Platelet dense granules contain Ca2+, serotonin and other biogenic amines, ADP and ATP, secreted in the release reaction. Ca2+ ions are triggering factors in the formation of a platelet clot, spasm of blood vessels and acceleration of blood coagulation. Biogenic amines induce only primary aggregation [28]. The use of serotonin antagonists and the activation of catabolism enzymes of vasoconstrictor biogenic amines to eliminate the spastic component of ischemia seems to be a promising direction for the pathogenetic treatment of atherosclerosis.

Thus, the functioning of the cardiovascular system is carried out according to the neuro-humoral regulatory mechanism, and the development of pathological conditions occurs with the involvement of various types of metabolism and cellular structures. The adhesion-aggregation activity of platelets has a significant effect on the occurrence of thrombosis. As a result of platelet adhesion and aggregation, hemostasis is realized in small vessels. The emergence of adhesion is promoted by a change in the vascular wall, contact of platelets with collagen fibers, the release of ADP, biogenic amines, and traces of thrombin from damaged cells. Against the background of adhesion, platelet aggregation occurs, which is stimulated by ADP released from the formed elements of the blood as a result of the destabilization of their membranes under the action of prothrombinase. Platelet activation is a key step in the haemostatic process. Therefore, platelet activation is an essential stage of thermogenesis and vascular lesions [26,27].

The anti-atherogenic properties of the derivative of sulfur-containing amino acids Tau may be due to the fact that the synthesis of taurocholates promotes lipid absorption, lipolysis, and absorption of fatty acids in the intestine. On the other hand, conjugation of taurine (Tau) with bile acids affects the elimination of cholesterol from the body and thereby controls cholesterogenesis [28]. When rats are kept on a high-fat diet supplemented with Tau, the latter inhibits the rise in cholesterol in the liver, inhibiting its intestinal absorption. In addition, at a dose of 250 and 500 mg / kg body weight, Tau activated the transport of cholesterol from the blood and its metabolism to bile acids [19]. Adding 300-500 mg of Tau to the diet reduces the concentration of bile acids and cholesterol in monkey bile and enhances the synthesis of taurocholates in piglets [20]. It is possible that the high level of taurocholates in some species of mammals (rats) complicates the modeling of experimental atherosclerosis, because the rate of exchange of bile acids increases due to the formation of chlortalurin.

The anti-atherogenic effect of S-adenosylmethionine, evaluated by increasing the level of glutathione and improving macro- and microcirculation, was investigated against the background of the atherogenic effect of cholesterol [60]. S-adenosylmethionine is recommended as an additive in amino acid mixtures for parenteral nutrition. Currently, the best known commercial preparations of S-adenosylmethionine in Europe are Samyr, Samet and Gambrel. Summarizing the above, it should be noted that the use of amino acid preparations for atherosclerosis is rational and the strategy for their use should be based on the elimination of the amino acid imbalance present in this disease, and the correction of the free sulfur-containing amino acids stock, including the use of taurine, whose anti-atherogenic properties should be considered quite promising [1-18].

Recently, new evidence has been obtained of the participation of amino acids in the pathogenesis of atherosclerosis. Thus, data were obtained on changes in extracellular levels of neurotransmitter amino acids during atherosclerotic brain damage - an increase in the concentration of both excitatory (glutamate, aspartate) and inhibitory amino acids (GABA and taurine) compared with the control [29].

It should be borne in mind that amino acids are not only important precursors for the synthesis of proteins and other N-containing compounds, but also participate in the regulation of the main metabolic pathways. For example, glutamate and aspartate are components of the malate / aspartate shunt, and their concentrations control the rate of mitochondrial oxidation of glycolytic NADH. Glutamate also controls the rate of urea synthesis not only as a precursor to ammonia and aspartate, but as a substrate for the synthesis of N-acetyl glutamate, a significant activator of carbonyl phosphate synthase. This mechanism allows the regulation of urea synthesis at a relatively constant concentration.

Certain amino acids (leucine) stimulate protein synthesis and inhibit autophagy degradation of the protein regardless of changes in cell volume, since they stimulate motor and protein kinase, which is one of the components of signal transduction of insulin. In the case of low energy supply of cells, motor stimulation with amino acids is inhibited by activation of camp-dependent protein kinase. Amino acid-dependent signaling also promotes insulin production by β-cells. This stimulates the anabolic effect of amino acids [30].

It is well known that the heart is “metabolically omnivorous” because it is able to actively oxidize fatty acids, glucose, ketone bodies, pyruvate, lactate, amino acids and even its structural proteins (in decreasing order of preference). The energy of these substrates provides not only mechanical contraction, but also the operation of various Tran’s membrane pumps and conveyors necessary to maintain ionic homeostasis, electrical activity, metabolism and myocardial catabolism. Cardiac ischemia and the resulting coronary and heart failure alter both the electrical and metabolic activity of the myocardium. The preference for substrates has been little studied, although hypoxia during ischemia significantly changes the relative selectivity of the heart in the use of different substrates. Metabolic changes in
heart rhythm disturbance are the main component of cardiac myopathies. At the same time, the potential contribution of amino acids to maintaining the electrical conductivity of the heart and stability during ischemia is underestimated. Despite the obvious evidence that amino acids have a cardio protective effect in ischemia and other cardiac disorders, their role in the metabolism of the ischemic heart has not yet been fully elucidated [31-33].

Studies on the determination of taurine and a number of amino acids predominant in the myocardium (glutamate, aspartate, glutamine and asparagine) in coronary insufficiency showed their differences in the content in the left and right ventricles in coronary insufficiency. A comparison of the levels of these amino acids in aortic stenosis and coronary heart disease in myocardial biopsy specimens showed higher concentrations of taurine in the left ventricle in both situations [34]. With severe, progressive cardio sclerosis in the rabbit myocardium, the content of phenylalanine and tyrosine increased, which was also found in patients with coronary heart disease, and the degree of increase in the level of amino acids changed depending on the clinical forms of coronary atherosclerosis (angina pectoris of various functional classes, myocardial infarction).

Methionine is a key essential amino acid, a donor of methyl groups and sulfur. It takes an active part in the metabolism of carbohydrates, fats and amino acids, the activation of antioxidant and detoxifying systems. Methionine serves as an essential precursor of cysteine, glutathione, taurine and, as a cysteine precursor, is involved in the synthesis of insulin and coenzyme A. Methylation processes (involving S – adenosylmethionine) are associated with gene expression, the functioning of the sympathoadrenal system, and the formation of choline and acetylcholine [34].

With regard to coronary heart disease, a special role is played by violations of the formation of methionine, leading to the accumulation in the blood and urine of its predecessor, homocysteine. Examination and treatment of patients with homocysteinuria revealed early and active development of atherosclerosis in young patients: hyperhomocyst(e)ines, a specific form of homocysteine. Examination and treatment of patients with homocysteinuria revealed early and active development of atherosclerosis in young patients: hyperhomocyst(e)ines, a specific form of homocysteine. Studies of patients with hyperhomocyst(e)ines, a specific form of homocysteine, revealed that the content of amino acids changed depending on the clinical forms of coronary atherosclerosis (angina pectoris of various functional classes, myocardial infarction).

Lysine is involved in the formation of collagen, the strengthening of the vascular wall, in the formation of carnitine, promotes the utilization of fatty acids for the energy potential of cells and the preservation of the body’s immune reactivity. When the artery walls rupture, the collagen threads connected to each other via lysine separate and prostrate into the vascular lumen, like the lysine residues, and are washed by the circulating blood. Lipoprotein A, a specific form of cholesterol present in the bloodstream, has receptors for lysine, binds to it and penetrates the intima of blood vessels, thus starting the process of generating hydrogen peroxide and superoxide radicals. Arginine, a semi-essential amino acid, serves as a precursor to nitric oxide, which affects platelet aggregation and adhesive ability, reducing the ability to thrombosis and reducing the vascular reactivity of atherosclerotic altered arteries and promotes the formation of collagen in the walls of blood vessels [35].

Adding 11 essential amino acids to the diet of the elderly, including arginine in amounts of 11 g. Within 2 weeks, it led to a decrease in the level of lipids, cholesterol, LDL and triglycerides in the blood plasma, exerting an anti-atherosclerotic effect [36]. It is known that the lipid content in blood plasma is controlled not only by the amount of dietary fats and carbohydrates, but also by dietary protein and amino acids. The source of such a protein is believed to be important. It is shown that, in addition, the amino acid and peptide composition of dietary protein is also of great importance. Sulfur-containing amino acids (SAA) are recognized as one of the most powerful modulators of lipid metabolism in a number of amino acids. SAA has been shown to act on HDL (high density lipoprotein) cholesterol and lower LDL (low density lipoprotein) lipoprotein. SAAs have some beneficial effects in atherosclerosis and related diseases (metabolic syndrome). The relative availability of SAAs, as well as the amount of SAA in diet proteins, determine lipid metabolism. Although it is not completely clear how SAAs affect gene expression and lipid metabolism at the molecular level, it has been proven that SAAs act on metabolism through activation of transcription and post-translational modification of a number of regulatory proteins [37].

Taurine inhibits the development of atherosclerosis, has an anxiolytic effect, which is realized indirectly through its systemic effect on the synthesis of 5-HT and GABA. This amino acid has a depressant effect in the central nervous system, inhibiting neuronal activity in the spinal cord and brain [38]. Soy protein (hypcholesterolemic effect), unlike casein with a hypercholesterolemic effect, contains a greater amount of arginine and glycine and causes an increase in the content of plasma arginine and glycine. Soy protein induces a low insulin / glucagon ratio in both patients with hypercholesterolemia and normocholesterolemic situations. Casein causes a high insulin / glucagon ratio among patients with hypercholesterolemia. Amino acids (arginine and glycine) induce a decrease, lysine and branched amino acids - an increase in serum cholesterol. It has been hypothesized that the control of cholesterol by insulin and glucagon is regulated by dietary and endogenous amino
acids. The insulin / glucagon ratio is proposed as an early metabolic index of the influence of food proteins on serum cholesterol levels, a risk factor and the general mechanism by which nutrition factors influence the development of atherosclerosis and cardiovascular disease [38,39].

In the blood plasma of patients with endothelial disorders in atherosclerosis, the levels of citrate, GABA, glutamate and cysteine were significantly different in comparison with myocardial ischemia in the context of glutamate and phenylalanine. On this basis, a differential diagnosis of aortic damage with coronary heart disease is considered possible [40].

The human heart uses a large number of free amino acids as regulators of both myocardial protein metabolism and energy metabolism [41]. The dependence of the myocardium on the amino acid fund of the heart increases with heart failure due to the high activity of the anabolic in the myocardium and the lack of energy for cardiomyocytes. Anabolic reactions in the heart are dependent on the oxidation of fatty acids and glucose. Normally, the functional activity of the Krebs cycle is significantly dependent on the concentration of amino acids. Free amino acids are stimulators of mitochondrial energy under anaerobic conditions, and also contribute to the substrate supply of cycle. Essential to the availability of heart amino acids is that their absorption by the myocardium depends solely on their arterial levels. The content of BCAA amino acids (branched chain) in myocardial metabolism is the most significant activator of anabolism in the heart, the level of which is not dependent on insulin. A slight increase in arterial amino acids leads to a significant increase in myocardial uptake. Amino acids play a crucial role in the metabolism of proteins and heart energy. In heart failure, the arterial pool of free AA, which is the determining factor in the absorption of amino acids by the myocardium, has not been practically studied. So, in comparison with the control, arterial amino acid levels were reduced in patients with heart failure. This decrease was associated with the severity of chronic heart failure and left ventricular dysfunction, in particular the level of aspartic acid [42].

A plant-based protein diet with a low Lys: Arg ratio has a beneficial normalizing effect on total serum cholesterol, LDL and adiponectin. To assess atherosclerosis, the Met: Gly ratio is also used. Amino acids as transceptors and regulators of nutrient fluxes by the mechanism of action on the metabolic fluxes of intracellular and extracellular concentrations of amino acids on motor proteins [43].

Amino acids are currently becoming increasingly widely regarded as cardio protective substrates that promote metabolism in the heart under anaerobic conditions and hypoxia through their participation in metabolic processes [44]. The specificity, ionic dependence, and kinetic properties of the amino acid transport systems identified in endothelial cells were compared and the regulation of the transport of vascular tone modulator by nitric oxide (NO) during hypoxia was studied. The transfer of L-arginine to endothelial and smooth muscle cells is modulated by otherrogenic lipids. The joint localization of the cationic transporter of amino acids CAT-1, nitric oxide synthase (eNOS) in endothelial cells, which provides a new mechanism for regulating the formation of NO when L-arginine enters the bloodstream, has been proven [45].

The “homocysteine” theory of arteriosclerosis was recognized when it was shown that after exogenous methionine loading, the concentration of homocysteine and cysteine was higher in patients with cardiovascular disease compared with a healthy control. Increased homocysteine levels have been demonstrated in coronary artery disease and atherosclerosis. It was found that in mice consuming a methionine-enriched diet a significant athermanous aortic pathology was observed even at normal plasma homocysteine levels [46].

The development and progression of atherosclerosis, which ultimately leads to cardiovascular disease, is causally associated with hypercholesterolemia. Mechanically, the interaction between lipids and the immune system during the progression of atherosclerotic plaques contributes to the chronic inflammation observed in the artery wall during atherosclerosis. Localized inflammation and increased intercellular interaction can affect the polarization and proliferation of immune cells through changes in amino acid metabolism. In particular, the amino acids L-arginine (Arg), L-homoarginine (hArg) and L-tryptophane (Trp) have been extensively studied in the context of cardiovascular diseases, and their effect has been established as key regulators of vascular homeostasis, similar to the functions of immune cells. Cyclic effects between endothelial cells, congenital and adaptive immune cells occur with a change in the metabolism of Arg, hArg and Trp, which have a significant effect on the development of atherosclerosis. Thus, the metabolism and biological functions of Arg, L-homoarginine, and Trp allow them to be reasonably used for the treatment of atherosclerosis [47-48].
